#### INTRODUCTION.

This bulletin presents data on costs and farm practices in the production of potatoes in nine surplus-producing areas in Maine, New York, Michigan, Wisconsin, and Minnesota; the relation of production in these areas to the production of the entire country; and the trends of production, prices, and costs for the past quarter century.

Over a series of years, considerable variations exist in acreage, yield, prices, and production costs, and a knowledge of the variations which have occurred in these factors and trends at the time the investigation was made should enable the individual grower to apply more intelligently the information contained herein to his own conditions.

Good business management on the part of the producer involves not only a thorough understanding of production costs and practices, but also an understanding of the forces and conditions governing the market.

## GEOGRAPHIC DISTRIBUTION OF POTATO PRODUCTION.

## ACREAGE.

The potato crop is widely distributed throughout the United States. The larger part of the commercial crop, however, is confined to relatively limited areas particularly suited to its production. The leading potato States in order of acreage are New York, Michigan, Wisconsin, Minnesota, Pennsylvania, and Maine. (See Table 1.). The major portion of the crop is grown north of a line running through Washington, D. C., and Chicago. (See fig. 1.)

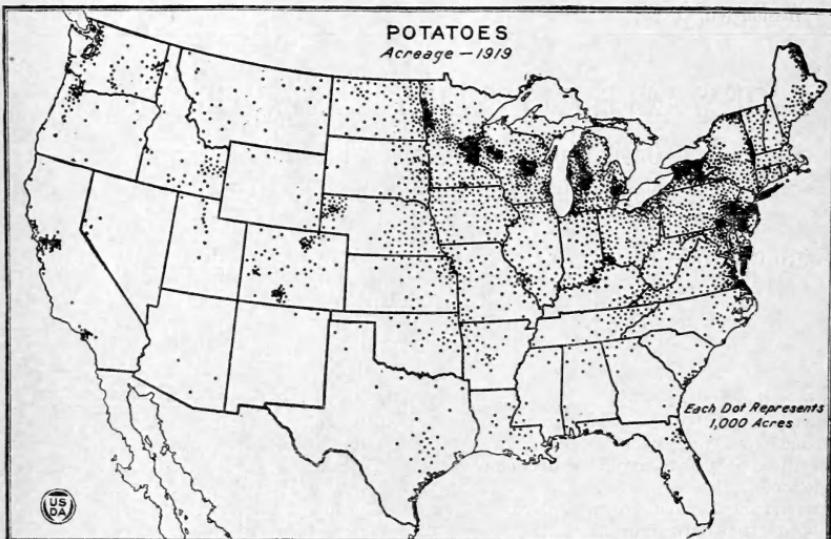

FIG. 1.—Potatoes are grown throughout the United States, but mainly in the northern tier of States. Elsewhere the areas of heavy production are small and widely scattered.

A relatively small proportion of the improved land in farms, for the four leading potato States, was in potatoes—only about 1.5 per cent. It is thus fairly easy to increase or decrease the potato acreage appreciably in these States. Table 1 shows that in individual States this variation does take place. In New York, for instance, the acreage in 1917 was one-fourth greater than in 1916. A large increase will also be noticed in Maine for 1917. The variation in total acreage for the United States is not so marked for successive years, indicating that the forces causing changes in acreages do not have the same effect in all States in any one year. (See fig. 2.)

**ACREAGE YIELD PER ACRE,  
AND PRODUCTION OF POTATOES

## PRODUCTION.

The six leading potato-producing States harvest nearly half the total crop of the country. No direct tendency toward increased production has been observed in these States during the nine years 1913 to 1921, inclusive. The acreage increased in Wisconsin and Minnesota, but lower yields held down the total production. Production has increased in a few of the Southern States, notably Virginia. Centers of production, however, have not changed materially during the past nine years.

## YIELDS PER ACRE.

Maine regularly leads in yield per acre, a result of climate and soils admirably adapted to potato production and the use of large quantities of commercial fertilizers. The average yields of New York, Wisconsin, and Minnesota were practically the same during the nine-year period. Yields were somewhat higher in New Jersey than in the States just mentioned, while those of Pennsylvania and the Central Western States were appreciably lower. In the extreme Western States, where the crop is raised mainly under irrigation, high yields are obtained. Idaho leads these Western States with a nine-year average yield of 162 bushels per acre, which is considerably below Maine's average of 204 bushels.

## PRODUCTION AND PRICE TRENDS.

The production of potatoes has more than kept pace with the population.<sup>2</sup> The average annual production per capita from 1869 to 1895 was 3 bushels and from 1896 to 1921 it was 3.5 bushels. This is significant. The increasing demand is being met by production in this country. Our imports of potatoes are relatively unimportant. The largest imports for any one year occurred in 1911, when the imports exceeded the exports by 12,500,000 bushels, amounting to about 4 per cent of the total number of bushels consumed. In short crop years the imports usually vary from 1 to 2 per cent of domestic production.

The lines of secular trend in Figure 3 indicate that total production has increased more rapidly than acreage and that both have increased more rapidly than population. The average yield per acre has been increasing as well as the production per capita.

The variation in production of potatoes from year to year has been marked, as indicated in Figures 2 and 3. Yields per acre have fluctuated more widely than acreages and production tends to follow yields more closely than acreage. An increase of 25 per cent in yield per acre over that of the previous year has not been uncommon, while a 10 per cent increase in acreage has been unusual.

The average yields for the United States seem to fluctuate in a series of cycles requiring two or three years for the completion of each cycle. The first cycle in Figure 2, for instance, is from 1896 to 1899, from the first high point to the succeeding high point in the yield-per-acre curve. The next cycle also required three years, the following high point not being reached until 1902. The range from the high to the low points of the cycles varies, but the regularity with which they occur is of more than passing interest. The striking thing is that the production varies consistently with the yield per acre and practically as widely. The acreage varies from year to year, but not as markedly as the yield per acre. In 75 per cent of the variations the yield moves in the same direction as the acreage, indicating that the factors which induce increase in acreage also influence the grower to work for a better yield.

The yields per acre in individual States (fig. 2) do not always move in the same direction as the United States yields. In 1919, for instance, when the United States yield was 93 per cent of the 10-year average, the Maine yield was 121 per cent, and in 1917, when the United States yield was 104 per cent, the Maine yield was 68 per cent. Similar variations may be noted in other States.

The farm price<sup>3</sup> per bushel varies inversely with the total production (see fig. 4) with few exceptions. The big variation in production for different years has been pointed out. When the production is relatively high the average price is relatively low and vice versa. It is the total production of the country that determines the price and not the production of any one State. Years of high potato prices

<sup>2</sup> The relations that have existed in the past between population, potato production, acreage, yields per acre, and price per bushel are shown in Figures 2, 3, and 4. A logarithmic scale was used in Figures 2 and 4, so that equal proportional changes are represented by equal vertical distances on the chart. An arithmetic scale was used in Figure 3, and the straight lines represent the long-time (secular) trend of potato production and acreage.

<sup>3</sup> The farm price is the Dec. 1 price as published by the United States Department of Agriculture.

have usually been followed by years of high production, resulting in low prices for those years, and conversely years of low production have been followed by years of high prices. (See fig. 4.) For the 25 years shown in this chart there were only seven exceptions to this rule.

The acre value of the crop does not vary as widely as the production or the bushel price. This is to be expected, since yield is usually

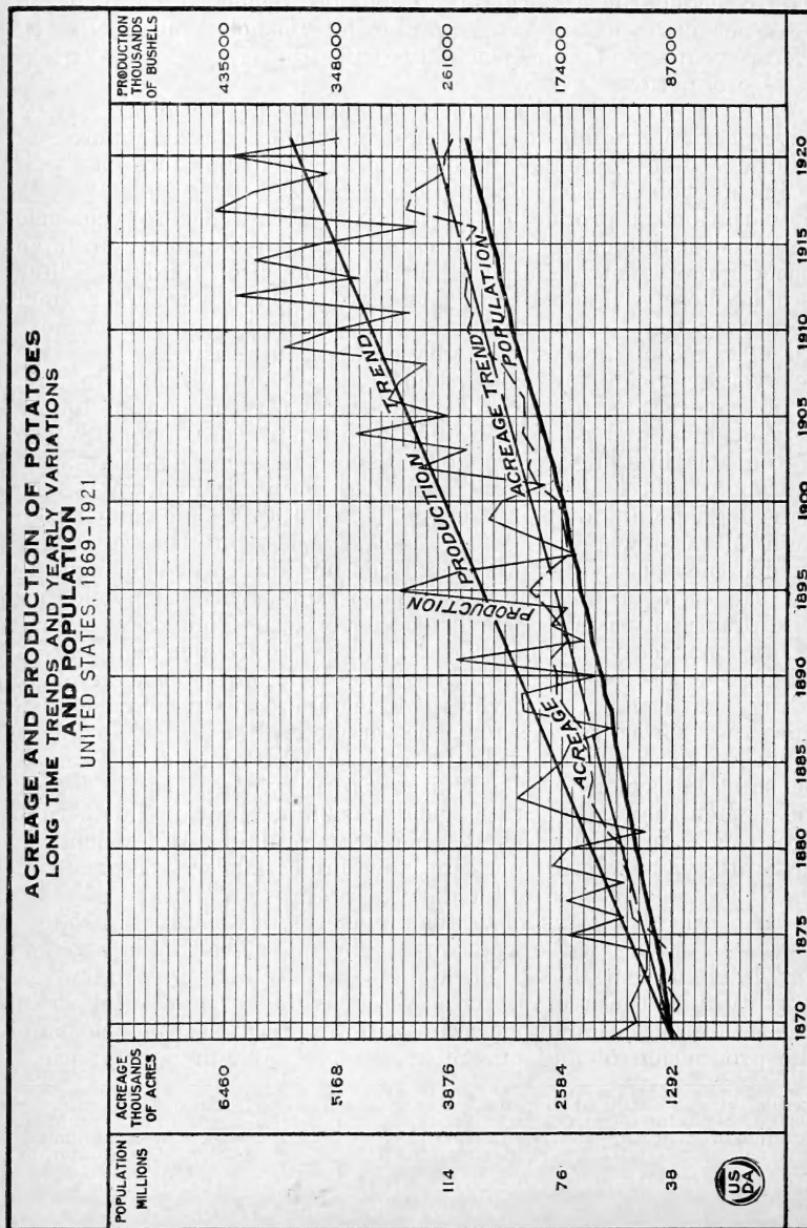

FIG. 3.—The acreage of potatoes has been increasing slightly faster than the population. Production has increased much faster than population though the annual fluctuations in production are wide, and tend to obscure the relations of the movements in short periods of time.

high when the price is low. The variations observed, however, are more generally in the direction of the price fluctuations than in the direction of the yield or the production fluctuations. The acre value for individual areas or individual farmers will increase or decrease in relation to the deviation from the United States yield. The price per bushel and the acre value for the United States have been gradually increasing since 1896, and, of course, they assumed a much higher level during the World War period, due to the increase in the general price level.

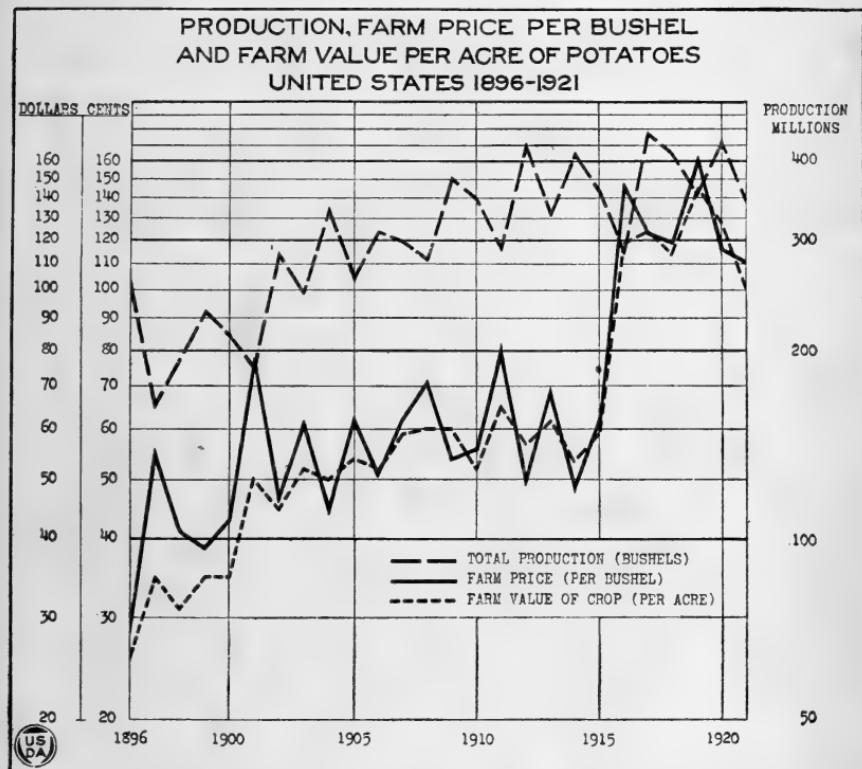

FIG. 4.—The influence of changes in total production of potatoes on the farm price from year to year is marked. The farm value per acre of potatoes is further affected by the yields per acre.

#### CONDITIONS PECULIAR TO SURPLUS PRODUCTION OF POTATOES.

Potatoes are raised in every State, but there are only about six States in which potato growing is consistently profitable enough to encourage an annual surplus of significant proportions. Combinations of conditions prevail in these areas of surplus production which result in a cost per bushel, year after year, too low for other areas to meet successfully on any great quantity of potatoes.

The fact that the annual crop of potatoes must be sold within the year, usually within nine months, and that in a good season the total production may easily be so large that it can be disposed of by growers only at a price which makes potatoes a comparatively cheap food, makes it relatively unprofitable, over most of the country, to grow more than local supplies, or a part of local supplies, and tends

to localize the surplus production in those areas where the cost on the farm is relatively low and where the cost of transportation to consuming centers is also relatively low. To be relatively profitable, therefore, the following conditions must usually obtain: (1) A low unit cost of production; (2) a freight rate which will leave an acceptable margin to growers at their shipping point.

#### COST OF PRODUCTION.

Low cost per bushel is the result of low cost per acre with ordinary yields, or with increasingly higher yields, as the cost per acre increases. The average yield of potatoes in the United States is about 100 bushels to the acre, but, as will be shown later, the growers of Aroostook County, Me., with costs per acre double those of most other areas, produce the crop at a cost per bushel as low as in most other areas, because their average yield per acre is double that of these other districts.

#### TRANSPORTATION CHARGES.

Without going into complete details with respect to the relation of transportation charges to farm prices for potatoes and their effect on localizing production in certain areas, it is obvious that the transportation charges, which are a product of the freight rate and the distance to the market, are a limiting factor. Thus, with equal costs per bushel at the farm or shipping point, those areas nearest to market have a distinct advantage. The effect of transportation charges on the distribution of the crop is illustrated by the figures in Table 2. The shippers in Cadillac, Mich., are, for example, at a disadvantage in shipping to Chicago as compared with central Wisconsin shippers, but they have a distinct advantage in the Detroit and Pittsburgh markets. In 1920 and 1921 the Maine growers had a differential of 18.6 cents a bushel against them in selling in the New York market as compared with shippers around Rochester, N. Y., but had an advantage in the New England markets. Potato growers in the South overcome the disadvantage of the high transportation charges to northern consuming centers because they can put their crop on the market at a high price compared with the stocks out of storage from the northern producing centers.

It will be observed in Figure 1 that large potato-producing areas are relatively near the most densely populated sections. The greatest number of large cities are located north of the latitude 39° and east of the ninety-seventh meridian. The most important potato-producing sections are also located within these limits. Potatoes constitute a bulky and perishable product, so that long hauls on railroads are not always profitable. Similarly, farms located long distances from the shipping station are seriously handicapped with high marketing costs.

#### COSTS AND PRACTICES IN 1919 ON SPECIFIC FARMS.

##### GENERAL CONDITIONS.

It has been pointed out that factors affecting the cost of producing a bushel of potatoes in different parts of the country vary

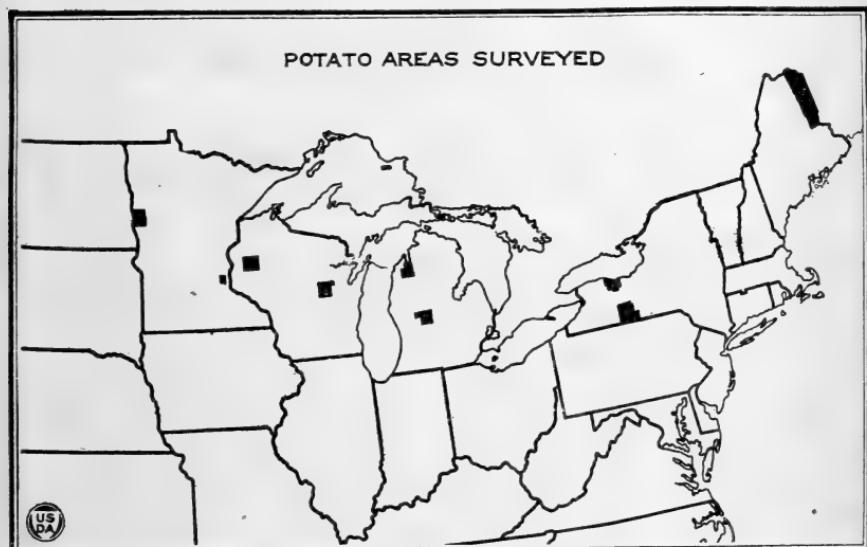

FIG. 5.—Nine counties in the areas of heaviest production were selected for study, together representing the conditions and practices prevailing in the production of potatoes over most of the northern humid regions.

considerably. Detailed costs and farm practices involved in potato production in nine different areas were studied in 1919 in order to show the effect of these differences. About 50 farmers were visited in each of these nine areas in the course of collecting the data presented in the following pages. The data apply to the crop year 1919. The areas studied are located in the following counties and States: Clay and Anoka Counties, Minn.; Barron and Waupaca Counties, Wis.; Grand Traverse and Montcalm Counties, Mich.; Monroe and Steuben Counties, N. Y.; and Aroostook County, Me. (See fig. 5.)

##### CLIMATIC CONDITIONS.

The precipitation for the months of the growing season, 1919, is shown in Table 3. The deviation of the 1919 rainfall from the normal was considerable in a few of the areas for some months. The

distribution of the rainfall throughout the month could not be shown, although this may be important in affecting yields, for there may be excessive rain for a short period of the month and no rain the rest of the month.

The 1919 yields on the farms studied were within 10 per cent of the average yield for the five preceding years in all areas excepting that of Monroe County, N. Y., where the 1919 yield was only 72 per cent of the normal. The low yield in this county was due primarily to the fact that the early part of the season was very wet and the latter part dry.

#### CROPS AND LIVE STOCK PRODUCED.

The area devoted to different crops in 1919 on the farms studied is shown in Table 5. Sixteen per cent of the crop acreage was devoted to potatoes, and for the several regions this percentage varied from 12 in Grand Traverse County, Mich., to 28 in Aroostock County, Me.

A fairly definite rotation of crops is followed in all the areas except in Clay County, Minn. Wheat, oats, and potatoes constitute the most important crops in this district and are not grown in any definite successions. In the other areas potatoes invariably follow clover or some other hay crop. Where corn is grown it follows potatoes; in other places a small grain follows. Corn is followed by a grain which is seeded to grass and completes the rotation. The most common short rotation is potatoes, wheat or oats, and clover.

The proportion of the farm receipts secured from different sources is shown in Table 6. Potatoes constituted the most important source of income in each area; in the Maine area, 94.5 per cent being derived from this source, and in the other areas ranging from 41.5 per cent in Barron County, Wis., to 64.8 per cent in Grand Traverse County, Mich. High prices were realized for potatoes in 1919 (see fig. 4) and consequently the proportional returns from the crop were relatively high.

TABLE 6.—*Proportion of farm receipts secured from different sources.*

Miscellaneous	.4	.8	.1	.1	.1	.8	.3	—	—

The relatively high receipts from potatoes in the Maine area were due chiefly to the high value of the potato crop per acre in 1919. Ninety-five per cent of the total receipts were secured from 28 per

cent of the crop area. Exceptionally high yields were obtained in 1919 and the price received was also high. The other crops, mainly hay and oats, were raised for feeding the stock and the small surplus of these crops sold gave relatively low returns per acre.

The livestock receipts were mainly from dairy cows. This is natural, since dairying and potato raising are carried on under similar climatic conditions and within reasonable distance of the large markets. Potatoes and dairy cows make a good combination from the farm organization point of view, as the cows consume roughage, furnish manure for the potato crop, and give opportunity for productive winter labor.

Livestock plays an important part in maintaining soil fertility in these regions. It utilizes the clover or other legumes that are grown in the rotation, thus permitting valuable plant food to be returned to the soil.

#### LABOR AND MATERIAL USED PER ACRE.

The average number of hours of labor spent per acre in potato production vary considerably in the different areas, as shown in Table 7. In Clay County, Minn., and Aroostook County, Me., the picking was usually done by contract labor, this work being paid for by the bushel or barrel. Information regarding the hours of labor required for this work was not obtained from sufficient growers to make the data usable for these areas. The normal yield, as given in Table 7, is the average of the farmers' estimates of what they considered normal yields for their farms. The county yields as obtained from census data are consistently lower than the yields of the farms studied for these States. This is to be expected, because the growers visited were located in areas where commercial growing had proved successful, while the county acreage includes potatoes grown in all types of soil by all kinds of growers.

## COST OF PRODUCTION.

A summary of the important items of cost in the production of an acre of potatoes for the areas studied is found in Table 8. The items of cost were charged at the rates prevailing during the year 1919. The yields used in computation were those obtained that year in each section.

Man and horse labor was the most important item of cost in all areas with the exception of Aroostook County, Me. In the Maine area the fertilizer cost was greater than the combined costs of man and horse labor.

The cost per acre for each item was computed by dividing the total cost for that item on the farms studied by the total number of acres, thus obtaining a weighted average for the region. This method resulted in a relatively low regional cost per acre for items that did not occur on the entire acreage. In the areas of Clay County, Minn., and Aroostook County, Me., for instance, manure was applied on only about one-third of the acreage planted to potatoes, resulting in a low charge for manure per acre when distributed over the total potato acreage. The costs of fertilizer per acre are low for the Barron and Montcalm areas for the reason that only one farmer in each area used fertilizer on his potato land.

A wide range will be noticed in the average costs per acre for the different regions studied. There is, however, a relatively slight range

in the average costs per bushel. The difference in yields tends to reduce the variation in cost per bushel. The high cost per bushel for the Monroe County, N. Y., area is due mainly to the low yield in 1919. The normal yield for this region is about 150 bushels per acre, but in 1919 the average yield obtained was only 110 bushels. With a normal yield the cost per bushel would compare favorably with the other sections studied. Many of the farmers in this region were within driving distance of Rochester, enabling them to realize higher prices for their potatoes than the farmers who had to ship. It is to be expected that the cost of producing potatoes in the important producing centers would not vary greatly when the transportation charges are the same.

#### VARIATION IN COST PER ACRE.

In Table 9 the farms have been grouped according to the cost per acre. The farms of Aroostook County, Me., are in a class by themselves. The extensive use of fertilizer and the high yields increasing the labor requirements result in high costs per acre. The variations in cost per acre in the other areas are more similar. Slightly more than one-third of the farmers produced the crop at a cost between \$80 and \$100 per acre, and about one-fourth of the farmers produced the crops at less than \$80 an acre.

### VARIATION IN COST PER BUSHEL.

The average cost per bushel for all farms was 78 cents for the year 1919. The number of farmers producing at certain costs and the cumulative percentage of the production at these costs are shown in Figure 6. Eighty-six per cent of the production was obtained at a cost of \$1 per bushel or less, and 71 per cent of the growers had costs of \$1 or less. The outstanding factor on the farms with extremely low costs per bushel was the yield. The costs per acre were also relatively low on these farms, but the high yields reduced the cost per bushel. Similarly, the farms with excessively high costs per

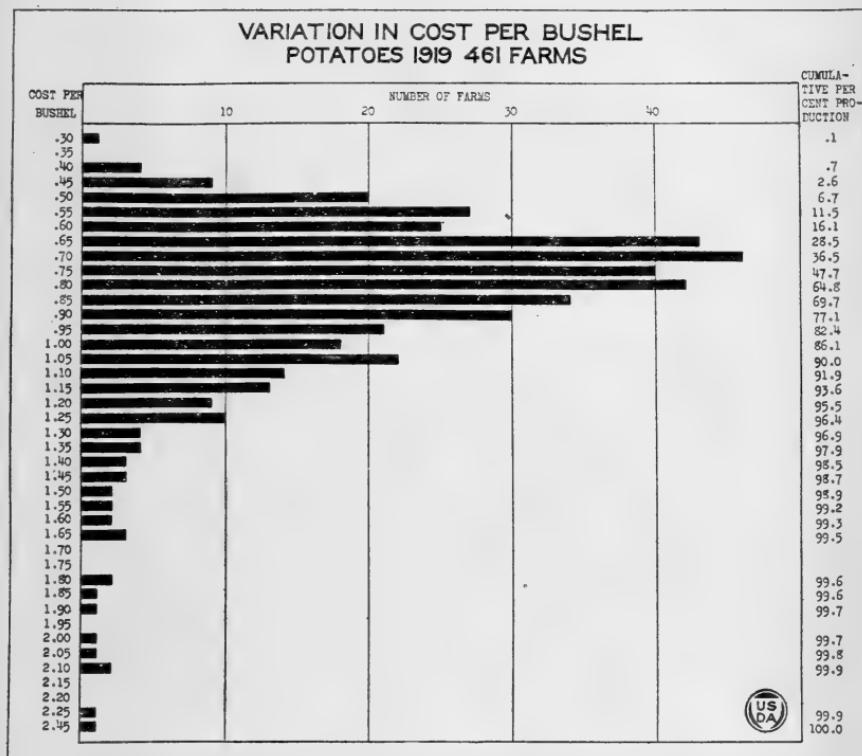

FIG. 6.—The cost per bushel of potatoes grown on 461 farms in 1919 ranged from 30 cents to \$2.45, with most of the farms producing at cost of \$1 or less per bushel.

bushel had extremely low yields per acre accompanied with relatively high costs per acre. With normal yields these high costs per bushel would have been cut in half.

### RELATION OF YIELD TO COST PER BUSHEL.

Yield per acre is an important factor affecting the cost per bushel, as has been previously pointed out. In Table 10 the farms are arranged in groups according to the yields, the table giving the relative yields and relative costs rather than the actual amounts. The yield and costs for each farm were reduced to the percentage that each was of the average for the area to which it belonged in order to place all farms on a comparable basis.

The table shows clearly that although the increased yields within these groups required greater costs per acre in labor and material, as well as greater total costs per acre, the additional bushels produced more than covered the additional costs and resulted in lower costs per bushel.

TABLE 10.—*Relation of yield per acre to costs,<sup>1</sup> per cent of average.*

<sup>1</sup> In preparing this table the items for each farm were expressed as percentages of the averages of the items for the area in which the farm was found.

### ANALYSIS OF ITEMS OF COST.

#### LABOR.

The rates per hour for man and horse labor used in computing the costs in the different areas are shown in Table 11. The rates for man labor are based on wages paid to hired labor plus the value of board consumed in the household. The operator's labor is computed at the same rate as hired labor. The rates for horse labor are based on cost-account records which had been taken in the different States under conditions similar to those prevailing in the sections where the potato studies were made.

TABLE 11.—*Man and horse labor rates per hour, 1919.*

	Minnesota.		Wisconsin.		Michigan.		New York.		Maine.

Man labor.....	\$0.40	\$0.35	\$0.34	\$0.32	\$0.32	\$0.30	\$0.30	\$0.32	\$0.38
Horse labor.....	.24	.20	.20	.20	.20	.20	.24	.24	.24

The cost of man labor and horse labor is dependent on two factors, namely, hours spent on the crop and the cost of this labor per hour. The hours of man labor were more nearly constant from year to year than were wages, which have fluctuated greatly during the past few years. Quantities, therefore, will be stressed in the following discussions of labor and of other items of cost. The variations in farm practices in growing potatoes, which affect the hours of labor required, are discussed under the following different operations: Manuring, preparation, planting, spraying, cultivating, harvesting, and marketing. The variations in the practices followed in the nine areas are shown in Tables 12 to 20. They show the usual as well as the unusual practices in each region. The most common crew in

these tables is practically the average crew for the region, though its rate of work is not necessarily exactly the average rate per day, which is based on the average instead of on the most common crew.

<sup>1</sup> Included in planting.<sup>2</sup> Barrels.<sup>3</sup> Contract.

The differences in practices on individual farms affect the hours of labor used in raising the crop. Tables 21 to 34 show the range in hours per acre for the different operations, indicating the number of growers who fall above and below the average hours per acre devoted to the different operations in the areas.

**Manuring.**—Manure usually was hauled from the barn to the field in manure spreaders, either during the winter as available or in the spring from the winter's accumulation. Occasionally a grower hauled the manure out during the winter with a wagon or sled and formed large piles, which were spread in the spring with a spreader. In the area of Clay County, Minn., only 33 per cent of the acres planted to potatoes were manured and in the area of Aroostook County Me., only 37 per cent. In all the other areas more than 75 per cent of the acres were manured. Nearly all the manure applied was produced on the farm.

*Preparation.*—Preparation included the operations of plowing, harrowing, rolling, and floating, or, in other words, getting the land in condition for planting. Plowing was the most important individual operation in preparing the land; 63 per cent of the man labor and 57 per cent of the horse labor in preparation were required for plowing. The average depth of plowing was 6.6 inches, varying from 4 to 10 inches. In the Minnesota and Wisconsin areas nearly half the harrowing was done with the disk, the remainder being done with the spike and spring-tooth harrow. In the Michigan, New York, and Maine areas about three-fourths was done with the spring-tooth harrow and the rest with the disk harrow. The spike-tooth harrow was used very little in preparation in these States.

*Planting.*—Planting included the operations of cutting, sprouting, and treating seed, marking of rows, applying fertilizer, and planting. The cutting of seed was done by hand. Fertilizer is usually applied at time of planting with potato planter. Not much seed was treated for skin disease. In hand planting the rows are marked off both ways with a horse marker and the potatoes are planted at the intersections of the marks with a hand planter. Hand planting was a common practice in a number of the areas.

In order to point out the differences in labor used, and results obtained between hand planting and machine planting, Table 35 is shown. In hand planting the spacing in the rows is usually wide enough to permit cultivating both ways. Thus less seed is used in hand planting than in machine planting. It is significant that the yield of potatoes is less and the cost of production greater on farms where planting is done by hand than on those planting with machine. This difference in yield and cost is probably due mainly to the difference in quantity of seed used (spacing is a factor in this), increased seeding usually resulting in increased yields, other things being equal.

TABLE 35.—*Hand planting vs. machine planting as affecting rate of planting, time required, yield and cost in growing potatoes (252 farms, 1919).*

Area.	Method of planting.	Number of farms.	Acres potatoes per farm.	Distance between rows.	Spacing in rows.	Hours planting.		Bushels seed per acre.	Average yield per acre.	Average cost per acre.	Average cost per bushel.

*Cultivation.*—Great variations exist in the methods of cultivation in the different areas studied. The first operation following hand planting is usually "recovering," or cultivating a ridge over the row, which is later harrowed level. This ridge covers seed which may not have been properly covered when planted and assists in controlling young weeds in the row. The size of crew varied from

one-row one-horse to two-row four-horse cultivators. The size of the outfit materially affects the man hours required per acre. The spike-tooth harrow and weeder are used to kill the young sprouts of weed seeds before and just as the potato plants appear above the ground. Considerable hoeing was done in a few of the areas.

*Spraying.*—Insecticides and fungicides were applied in the form of spray or dust. In the areas of Clay County, Minn., and Barron and Waupaca, Wis., considerable dusting was done. Spraying was the most common form of application in the other areas. For all areas about one-third of the spraying and half of the dusting were done by hand. In the areas of Waupaca, Wis., and Grand Traverse, Mich., most of the spraying and dusting was done by hand. In the area of Steuben County, N. Y., over half was done by hand. Of the 461 farmers visited, 410 sprayed or dusted their potato fields. The least spraying and dusting was done in the area of Steuben and Monroe Counties, N. Y. Only 38 out of 50 farmers in the former district and only 30 out of 50 in the latter district did such work.

*Harvesting.*—The harvesting of the crop required more man labor than any other operation connected with the growing of potatoes. Harvesting includes the digging, picking, and hauling to the barn. High yields increase the labor per acre, but reduce the labor per bushel over that required when yields are low. Hand digging is a common practice in Grand Traverse County, Mich., and Waupaca County, Wis. The difference in man labor per acre involved in hand digging and machine digging is strikingly shown in the labor practice tables. Potato picking by contract is the most usual practice in the areas of Clay County, Minn., and Aroostook County, Me. The average rate paid for picking in 1919 was  $8\frac{1}{2}$  cents a bushel in the former area and  $4\frac{3}{4}$  cents a bushel in the latter area.<sup>4</sup>

After picking, the potatoes were hauled directly to the shipping station, to storage place, which was usually the barn or the house, or were pitted temporarily in the field. The pitting and hauling to storage were considered a part of harvesting. Pitting was most common in the Wisconsin and Michigan areas.

*Marketing.*—About 11 per cent of the man labor and 18 per cent of the horse labor in producing potatoes are devoted to marketing. This includes the work of sorting and grading and hauling to market. Part of the crop is hauled directly from the field to market and part from storage to market. Table 36 shows how the crop is disposed of in the areas studied. A few of the growers in the areas of Anoka County, Minn., and Monroe County, N. Y., hauled their crops directly to the city market, but most of the potatoes were hauled to the shipping station and sold on the cars.

---

<sup>4</sup> In the Maine area the unit of potato measure is the barrel.

### SEASONAL DISTRIBUTION OF OPERATIONS IN POTATO PRODUCTION

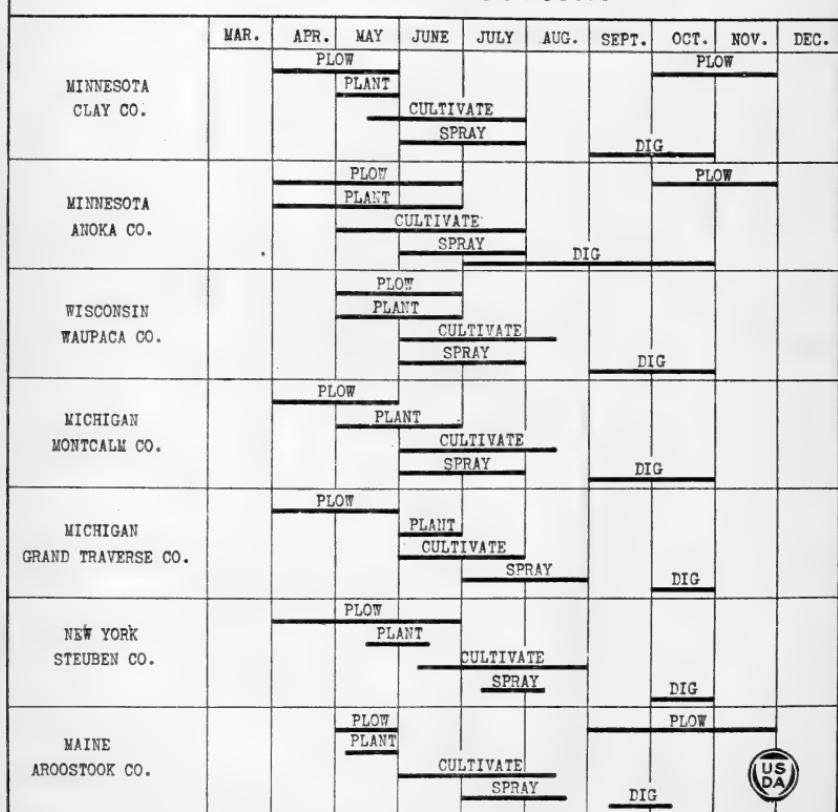

FIG. 7.—May, June, July, and October are the busiest months in the northern potato areas. The several preharvest operations overlap to some extent from farm to farm as well as from season to season, and in Anoka County, Minn., digging the early potatoes may be in progress before the main crop is laid by. Fall plowing was practiced by some growers.

*Seasons for various operations.*—The months in which the important operations in potato production are generally performed in the different regions are shown in Figure 7. Fall plowing was not generally

practiced outside the Minnesota and Maine areas. In the Anoka area a considerable quantity of potatoes is raised for the early local market, which accounts for the spread of the periods of operations. On the whole, the time for performing the different operations is very similar for all the areas. The major portions of the crops of these regions are available for the market at about the same time. The busiest months in growing potatoes are May, June, July, and October.

#### MATERIALS.

The items of production costs included under "Materials" are: Manure, seed, fertilizer, spray material, and seed-treatment material.

**Manure.**—An estimate was secured from each grower as to the number of tons of manure applied to the potato acreage and of the value of the manure at the barn. Manure was commonly applied with a manure spreader of standard size and it was thus not very difficult for the farmer to estimate the quantity applied.

Manure was usually applied to the potato crop. The applications were light in the areas of Clay County, Minn., and Aroostook County, Me., because of the limited supply for the large acreages grown in these areas. However, the application per acre was liberal for the acres covered.

Dairying was an important enterprise in all the areas excepting the Maine area and a large proportion of the manure used was produced on the farm. The value of the manure as given in Table 37 is the value per ton at the barn.

There were a few instances where rye or some other cover crop was sowed in the autumn to be plowed under the following spring as a green manure crop. In these cases the cost of seed and cost of labor of putting in the crop were charged against the potato crop. The plant food and humus value of sod plowed under for potatoes was not charged against the crop. Its value to the potato crop would be difficult to determine with any degree of accuracy, but the importance of a clover sod in the rotation is appreciated by all good farmers.

Per cent acres fertilized..	0	0	(1)	0	(1)	0	21	29	99

<sup>1</sup> One grower in this area used commercial fertilizer.

**Fertilizer.**—The purchase price, plus freight paid, was used as the cost of fertilizer. The individual grower has little difficulty in recalling the quantity of fertilizer applied per acre. The hauling was included in the labor charge.

The use of commercial fertilizer was practically limited to the New York and Maine areas. One grower in Barron County, Wis., and one in Montcalm County, Mich., were the only exceptions. In the Maine area a heavy application was used, a ton to the acre being the common rate. A high-grade fertilizer was used in this area as will be noted by the price in Table 37. The usual grade used was 4-8-4.<sup>5</sup> In the other areas acid phosphate was more commonly used.

*Seed.*—Only a small proportion of the seed used was purchased, as the common practice was to save the seed from the previous year's crop. The value of home-grown seed for purpose of these computations was the market price of seed on the farm at the time of planting.

The charge for seed constitutes from 10 to 16 per cent of the total cost, with an average for all areas of about 12 per cent. The average quantity of seed used per acre was 11.4 bushels for all areas. The large variation in some areas, indicated in Table 38, between the five growers using the least seed and the five using the most seed, per acre, was due mainly to the fact that both hand and machine planting were practiced in these areas, the hand planters using less seed.

TABLE 38.—*Quantity of seed used per acre—Potatoes, 1919 crop, 461 farms.*

Many different varieties of potatoes were grown. Many farmers grew more than one variety. Early Ohio and Cobbler were the most common varieties in the area of Clay County, Minn., and early Ohio and Triumph in the area of Anoka County, Minn. Rural New Yorker and Petosky were the important varieties in Barron and Waupaca Counties, Wis., and Montcalm and Grand Traverse Counties, Mich. The Green Mountain was also grown considerably in the Barron County area. The greatest number of varieties grown were in the area of Monroe and Steuben Counties, N. Y., though the leading varieties were Peerless Jr., S. W. Raleigh, and Carman. Cobbler and Green Mountain were the common varieties grown in Aroostook County, Me.

*Spray and seed treatment materials.*—Aside from the areas of Aroostook County, Me., and Monroe County, N. Y., the spraying was practically limited to poison sprays, Paris green, and other arsenic compounds. In the two areas mentioned Bordeaux mixture was used occasionally. Two and one-half times constituted the average

<sup>5</sup> That is, 4 per cent nitrogen, 8 per cent phosphoric acid, and 4 per cent potash, the order in which plant food formulas are quoted in many sections.

number of sprayings varying from four and one-half times in the Maine area to less than two times in the Clay County, Minn., area. The quantity of poison spray material used per acre varied considerably, ranging from 1 to 3 pounds per acre per spraying. About 2 per cent of the total cost of production was for spray material.

As a very small proportion of the growers visited treated the seed for scab or other skin diseases, this represents a negligible item of cost.

#### USE OF LAND.

The charge for use of land was determined by obtaining the sale value of the potato land and multiplying it by the prevailing rate of interest on farm mortgages. The charge was determined in this manner, whether the potato land was operated by the owner or rented on the cash or share crop basis, to put the individual farms on the same basis. This item does not include taxes, overhead expenses, and the consumption of fertility. It is the interest charge on land value and thus does not fully represent what might be termed the cash-rent charge. If one prefers not to include the use of land as a cost the charge may be readily eliminated.

The value of the potato land varied considerably on different farms due to location of farm, quality of land, and general improvement on the farm. The average acre-value of the potato land is given in Table 39 with the average for the highest five and the lowest five. In all areas the yields were higher on the higher priced land.

Lowest five.....	82	96	115	95	76	67	48	147	100

#### MACHINERY.

The use of farm machinery on the potato crop was charged at 8 cents per horse hour. This rate was based on the results obtained on detailed cost accounting records on potato farms in different sections of the country and probably represents a fair charge for this item. It includes repairs, depreciation, and interest on the inventory value of the machinery chargeable to the potato crop. It includes all machinery used on the crop. The most common special potato machinery consisted of a one-row two-horse planter, a potato sprayer or duster, and one elevator digger. Where soil and topographic conditions permit, the modern commercial potato grower has these special implements. Ten acres or more of potatoes undoubtedly justify the investment in these implements. Occasionally two or more small growers own a planter or sprayer in partnership.

## OVERHEAD.

In addition to items of expense which may be charged directly to the potato crop, there are certain general farm expenses of which the potato crop has to bear its proportionate share. These general expenses include such items as maintenance of buildings, lots, fences, roads, etc.; interest on the value of same; and miscellaneous cash expenses which can not be charged to any one enterprise on the farm. Detailed cost accounting records have established rates for this item and show it as a percentage of the combined labor and material costs. The rates applied in this study were 5 per cent for the Minnesota areas, 6 per cent for the Wisconsin and Michigan areas, and 8 per cent for the New York and Maine areas.

## OTHER COSTS.

*Taxes and insurance.*—The tax and fire insurance charge against the potato crop represents the proportion of the total farm expenses for these items that the potato land capital was of the total farm capital. The estimated total farm capital was obtained for each farm, as were also the total taxes and fire insurance paid, and the potato crop's share was thus readily determined. A few of the growers carried hail insurance and the actual cash cost of this insurance was used as the charge for crop insurance. Taxes and insurance constituted slightly less than  $1\frac{1}{2}$  per cent of the total costs.

*Bags and barrels.*—Containers were needed to carry the crop from field to storage and to market. Potatoes were very seldom shipped in containers. Bags and barrels bought during the year to handle the crops constituted the charge for this item of expense. A few of the growers shipped in bags in the area of Clay County, Minn., resulting in a relatively high charge for bags in this area.

*Storage charges.*—Some growers had separate potato-storage buildings, and when used wholly for storing potatoes the maintenance of the building was charged to storage. Any purchased fuel used was charged at cost, and if it was wood from the farm it was charged at the prevailing price of cut wood on the farm. Hired storage was charged at actual cost. Many growers store part of the crop in the dwelling or other farm buildings. No separate storage charge was made in such cases, as the overhead expense covered this item. Few potato-storage houses were found outside Clay County, Minn., and Aroostook County, Me. In these two areas, however, about half the growers visited had separate storage houses.

*Loss on abandoned potato acreage.*—On some farms part of the potato acreage was not harvested because of excessively wet weather, hail, insects, or fungous diseases, or other causes may have made digging not worth while. This charge, then, consists of the expenses on the abandoned acres, including labor, seed, manure, fertilizer, use of land, and other costs. The total cost of all abandoned acreage in a region, divided by the acreage harvested, is the average abandoned acreage cost per acre harvested. No instances were found where crop-insurance payments covered the item of loss on abandoned acreage.

## TENURE.

Of the 461 farmers visited, 345, or 75 per cent, owned all of the land they were operating; 63 rented some land in addition to the farms they owned; 45 rented the farms, including the potato land on shares; and 8 rented the farms for cash.

In regions where the tenant and landlord owned the machinery and livestock jointly it was customary for the tenant to furnish the feed and labor and receive half the crop. Where the landlord furnished only the land and seed it was not uncommon for the tenant to receive two-thirds of the crop. The most common sharing of the potato crop was half to landlord and half to tenant. There was, however, a great variation in sharing of expenses, depending upon the arrangement with respect to the other crops grown, the acreage in potatoes, and the quality of the land.

In studying the equitability of any share-rent arrangement in the growing of potatoes, Table 40 should be of assistance. It shows what proportion the cost of each important item is of the total cost. These proportions will vary somewhat from year to year, for individual items, because of variation in value. Adjustments, however, may be made when of sufficient importance to affect results. On individual farms the practices may be considerably different from that shown as an average for the region. With quantities and values given in other tables on which the data given in Table 40 are based, adjustments can be made readily. For individual farmers, then, this table should serve as a guide and not as a definite standard for all conditions.

<sup>1</sup> Less than half of 1 per cent.

<sup>2</sup> Land rent includes 6 per cent interest on estimated real estate value of the potato land and the proportional share of the taxes and fire insurance.

## RELATIONS OF COSTS AND PRICES 1913-1921.

The previous discussions have shown the marked variations from year to year in yields and prices received by farmers for potatoes. With the basic data of production requirements available for 1919,

as well as the cost per unit of labor and materials for different years, it is possible to determine the general trend of costs and prices for different years. Table 41 has been constructed on this basis.

The items which do not vary with yield, such as cultural labor, seed, fertilizer, and overhead, are assumed to be the same from year to year, varying only with the cost per unit. Harvesting and marketing labor and containers were increased or decreased according to the yields. The prices applied to these data were average prices for the State as reported by the Bureau of Crop Estimates, as were also the yields and prices received per bushel. The data in Table 41 should, therefore, not be taken as absolute costs but as trends of costs.

TABLE 41.—*Trend of cost per acre, cost per bushel, and price per bushel received, 1913–1921.*

1913....	43	.33	.50	51	.32	.53	46	.38	.55	56	.67	.82	107	.46	.55					

<sup>1</sup> For 1919 cost per acre and per bushel as obtained in this investigation, see Table 8.

Probably the most striking thing shown by this table is the marked variation in costs for successive years. The costs are usually high when the price received is low, and vice versa. Tables 42 and 43 are shown to point out the variation in two of the important contributing costs—seed and labor. The years with outstanding high seed-potato prices were 1914, 1917, and 1920, as shown in Table 42. By referring to Table 41 it will be observed that these were the years when the price received for the crop was relatively low per bushel. Similarly, in years when the seed cost was relatively low the margin between the cost of production and the price received was greatest. The grower who contemplates changing his acreage materially when seed prices are relatively high or low should carefully study acreage, yields, and prices in previous years when similar conditions prevailed, to see what normally may be expected before making his decision.
